Abstract

Recently, the state-of-the-art models for image captioning have overtaken human performance based on the most popular metrics, such as BLEU, METEOR, ROUGE and CIDEr. Does this mean we have solved the task of image captioning? The above metrics only measure the similarity of the generated caption to the human annotations, which reflects its accuracy. However, an image contains many concepts and multiple levels of detail, and thus there is a variety of captions that express different concepts and details that might be interesting for different humans. Therefore only evaluating accuracy is not sufficient for measuring the performance of captioning models – the diversity of the generated captions should also be considered. In this paper, we proposed a new metric for measuring diversity of image captions, which is derived from latent semantic analysis and kernelized to use CIDEr similarity. We conduct extensive experiments to re-evaluate recent captioning models in the context of both diversity and accuracy. We find that there is still a large gap between the model and human performance in terms of both accuracy and diversity, and the models that have optimized accuracy (CIDEr) have low diversity. We also show that balancing the cross-entropy loss and CIDEr reward in reinforcement learning during training can effectively control the tradeoff between diversity and accuracy of the generated captions.

1. Introduction

The task of image captioning is challenging and draws much attention from researchers in the fields of both computer vision and natural language processing. A large variety of models have been proposed to automatically generate image captions, and most of the models are engaged in improving the accuracy of the generated captions as measured by the current metrics, such as BLEU 1-4 [22], METEOR [7], ROUGE [16], CIDEr [28] and SPICE [1]. However, another important property, the diversity of captions generated for a given image, receives less attention. Generally, diversity refers to the differences among a set of cap-

Figure 1: An overview of our diversity metric. Given a set of captions from a method, we first construct the self-similarity matrix \( K \), consisting of CIDEr [28] scores between all pairs of captions. The diversity score is computed from the singular values of \( K \). A higher diversity score indicates more variety in the set of generated captions, such as changes in the level of descriptive detail and inclusion of removal of objects. The accuracy (average CIDEr) of the captions with respect to the human ground-truth is on the bottom. For human annotations, this is the leave-one-out accuracy. 

\( \text{Diversity Score} = \frac{\text{Accuracy Score}}{\text{Similarity Score}} \)
tions are as follows. First, an image may contain many concepts with multiple levels of detail — indeed, *an image is worth a thousand words* — and thus an image caption expresses a set of concepts that are interesting for a particular human. Hence, there is diversity among captions due to diversity among humans, and an automatic image captioning method should reflect this. Second, only focusing on increasing the caption accuracy will bias the captioning method to common phrases. For example, Figure 1 shows the set of captions generated by two models. Model 2 is the best when only considering accuracy. However, Model 2 just repeats the same common phrases, providing no particular additional details. In contrast, Model 1 recognizes that there are trees in the image and the grass is dry, which also occurs in the human annotations. It even recognizes “walking”, which does not appear in the human annotations, but is a plausible description. Thus, to mimic the ability of humans, the captioning models should also have the ability of generating diverse captions. Third, from the machine learning viewpoint, captioning models are typically trained on datasets where each image has at least 5 ground-truth captions (e.g., MSCOCO), and thus captioning models should also be evaluated on how well the learned conditional distribution of captions given an image approximates that of the ground-truth. In particular, while the caption accuracy measures the differences in the modes of the distributions, the caption diversity measures the variance of the distribution.

Recently, while a few works have focused on generating both diverse and accurate captions, such as conditional variational auto-encoders (CVAE) [30] and conditional generative adversarial network (CGAN) [5, 26], there is not a metric to well evaluate the diversity of captions. In [5], the diversity of captions is shown only qualitatively. [26, 30] evaluate the diversity of captions in three ways: 1) the percentage of novel sentences; 2) the percentage of unique uni-grams and bi-grams in the set of captions; 3) mBLEU, which is the average of the BLEU scores between each caption and the remaining captions. However, it is difficult to define a novel sentence, and only considering the percentage of unique uni-grams and bi-grams ignores the relationship between captions, e.g., the same n-gram could be used to construct sentences with different meanings. Because mBLEU uses the BLEU score, it aggregates n-grams over all the remaining captions, which obfuscates differences among the individual captions, thus under-representing the diversity. For example, the two caption sets, $C_1 = \{\text{“zebras grazing grass”}, \text{“grazing grass”}, \text{“zebras grazing”}\}$ and $C_2 = \{\text{“zebras grazing”}, \text{“zebras grazing”}, \text{“zebras grazing”}\}$, obtain the same mBLEU of 1.0. However, we may consider that $C_1$ is more diverse, because each of its captions expresses different concepts or details. In contrast, captions in $C_2$ describe exactly the same thing. Hence, considering all the pairwise relationships among captions will better reflect the structure of the set of captions. Moreover, BLEU is not a good metric for measuring semantic differences, since phrase-level changes and semantic changes may lead to the same BLEU score (e.g., see Table 1).

In this paper, we propose a diversity measure based on pairwise similarities between captions. In particular, we form a matrix of pairwise similarities (e.g., using CIDEr), and then use the singular values of the matrix to measure the diversity. We show that this is interpretable as applying latent semantic analysis (LSA) on the weighted n-gram feature representation of the captions to extract the topic-structure of the set of captions, where more topics indicates more diversity in the captions. The key contributions of this paper are three-fold: 1) we proposed a new metric for evaluating diversity of sets of captions, and we re-evaluate existing captioning models via considering both diversity and accuracy. Moreover, our proposed metric shows a stronger correlation to human evaluation than mBLEU; (2) we develop a framework that enables a tradeoff between diverse and accurate captions via balancing the rewards in reinforcement learning (RL) and the cross-entropy loss; (3) extensive experiments are conducted to demonstrate the effectiveness of the diversity metric and the effect of the loss function on diversity and accuracy – we find that RL and adversarial training are different approaches that provide equally satisfying results.

2. Related Work

**Image Captioning.** Early image captioning models normally contain 2 stages: 1) concept detection, 2) translation. In the first stage, object categories, attributes and activities are detected, then the translation stage uses the labels to generate sentences. The typical concept detection models are conditional random fields (CRFs) [9, 13], support vector machines (SVMs) [15] or convolutional neural networks (CNNs) [8], and the translation model is a sentence template [9] or n-gram model [15].

Recently, the encoder-decoder models, e.g., neural image captioning (NIC) [29], spatial attention [34] and adaptive attention [19], trained end-to-end have obtained much better results than the early models based on concept detection and translation. NIC [29] translates images into sentences via directly connecting the inception network to an LSTM. To improve NIC, [34] introduces a spatial attention module, which allows the model to “watch” different areas when it predicts different words. [10, 33, 35, 36] use image semantics detected using an additional network branch. In [19], a sentinel gate decides whether the visual feature or the semantic feature should be used for prediction. Instead of employing LSTM decoders for sentences, [2, 31, 32] apply convolutional decoders, which achieves faster training process and comparable results.

Both LSTM and convolutional models are trained using

</table>

Table 1: The similarity scores between a reference caption and a modified caption using different evaluation metrics. The caption in the first row is the reference caption, and the next five captions change different parts of the sentence (highlighted in bold) while keeping the same concepts. “Average” is the average metric value over these 5 modified captions. The bottom row shows an incorrect caption and the score below it is the average metric value. The metric scores, B1-4, M, R, C/10, and S are BLEU1-4, METEOR, ROUGE, CIDEr divided by 10 (so that the maximum is 1), and SPICE.

Table 1 shows an example of similarity metrics between a reference caption and 5 modified captions that have the same semantic meaning, and an incorrect caption with different meaning. All metrics are less sensitive (have higher values) to sentence-level changes (due to the use of n-grams), in particular BLEU, METEOR and SPICE. Furthermore, all metrics show sensitivity to word-level or phrase-level changes. Overall, CIDEr and METEOR have relatively low average metric value, which means that they are not sensitive to sentence changes that keep the same semantics. On the other hand, CIDEr and METEOR also assign lower values to the incorrect caption that changes the semantic meaning, which indicates that they are better able to discriminate between semantic changes in the sentence. Hence, in this paper, we mainly consider CIDEr as the baseline metric to evaluate both the diversity and accuracy.

3. Measuring Diversity of Image Captions

Currently, the widely used metrics, such as BLEU, CIDEr, and SPICE are for a single caption prediction. To evaluate a set of captions \( C = \{ c_1, c_2, \ldots, c_m \} \), two dimensions are required: accuracy and diversity. For accuracy, the standard approach is to average the similarity scores,
acc = \frac{1}{m} \sum_{i} s_{i}, \text{ where } s_{i} = \text{sim}(c_{i}, C_{GT}) \text{ is the similarity measure (e.g., CIDEr) between caption } c_{i} \text{ and ground-truth caption set } C_{GT}. \text{ For diversity, we will consider the pairwise similarity between captions in } C, \text{ which is able to reflect the underlying structure of the set of captions.}

3.1. Latent Semantic Analysis

Latent semantic analysis (LSA) [6] is a linear representation model, which is widely applied in information retrieval. LSA considers the co-occurrence information of words (or n-grams), and uses singular value decomposition (SVD) to obtain a low-dimensional representations of the documents in terms of topic vectors. Applying LSA to a caption set, more topics indicates a more diverse set of captions, whereas only one topic indicates a non-diverse set. To use LSA, we first represent each caption via a vector. In this subsection, we consider the simplest representation, bag-of-words (BoW), and kernelize it in the next subsection using CIDEr.

Given a set of captions \( C = \{c_{1}, \cdots, c_{m}\} \) that describe an image, and a dictionary \( D = \{w_{1}, w_{2}, \cdots, w_{d}\} \), we use the word-frequency vector to represent each caption \( c_{i} \), \( f_{i} = [f_{i1}, \cdots, f_{id}]^{T} \), where \( f_{ij} \) denotes the frequency of word \( w_{j} \) occurring in caption \( c_{i} \). The caption set \( C \) can be represented by a “word-caption” matrix, \( M = [f_{1} \cdots f_{m}] \).

Applying SVD, we decompose \( M \) into three matrices, i.e., \( M = U S V^{T} \), where \( U \) is composed of the eigenvectors of \( MM^{T} \) and \( S = \text{diag}(\sigma_{1}, \cdots, \sigma_{m}) \) is a diagonal matrix consisting of singular values \( \sigma_{1} > \sigma_{2} > \cdots > 0 \), and \( V \) is composed of the eigenvectors of \( M^{T}M \). Each column of \( U \) represents the words in a topic vector of the caption set, while the singular values in \( S \) represent the strength (frequency) of the topics. If all captions in \( C \) are the same, then only one singular value is non-zero, i.e., \( \sigma_{1} > 0 \) and \( \sigma_{i} = 0, \forall i > 1 \). If all the captions are different, then all the singular values are the same, i.e., \( \sigma_{1} = \sigma_{i}, \forall i \). Hence, the ratio \( r = \frac{\sigma_{1}}{\sum_{i=1}^{m} \sigma_{i}} \) represents how diverse the captions are, with larger \( r \) meaning less diverse (i.e., the same caption), and smaller \( r \) indicating more diversity (all different captions). The ratio \( r \) is within \([\frac{1}{m}, 1]\). Thus we map the ratio to a value in \([0, 1]\), to obtain our diversity score \( \text{div} = -\log_{m}(r) \), where larger \( \text{div} \) means higher diversity.

Looking at the matrix \( K = M^{T}M \), each element \( k_{ij} = f_{i}^{T} f_{j} \) is the dot-product similarity between the BoW vectors \( f_{i} \) and \( f_{j} \). As the dimension of \( f_{i} \) may be large, a more efficient approach to computing the singular values is to use the eigenvalue decomposition \( K = VA\Lambda V^{T} \), where \( \Lambda = \text{diag}(\lambda_{1}, \cdots, \lambda_{m}) \) are the eigenvalues of \( K \), which are the squares of the singular values, \( \sigma_{i} = \sqrt{\lambda_{i}} \). Note that \( K \) is a kernel matrix, and here LSA is using the linear kernel.

3.2. Kernelized Method via CIDEr

In Section 3.1, a caption is represented by BoW features \( f_{i} \). However, this only considers word frequency and ignores phrases and sentence structures. To address this problem, we use n-gram or p-spectrum kernels [25] with LSA. The mapping function from the caption space \( C \) to the feature space \( F \) associated with the n-gram kernel is

\[
\phi_{n}(c) = [f_{1}^{n}(c) \cdots f_{|D^{n}|}(c)]^{T},
\]

where \( f_{i}^{n}(c) \) is the frequency of the \( i \)-th n-gram in caption \( c \), and \( D^{n} \) is the n-gram dictionary.

CIDEr first projects the caption \( c \in C \) into a weighted feature space \( F \), \( \Phi_{n}(c) = [\omega_{i}^{n} f_{i}^{n}(c)] \), where the weight \( \omega_{i}^{n} \) for the \( i \)-th n-gram is its inverse document frequency (IDF). The CIDEr score is the average of the cosine similarities for each \( n \),

\[
\text{CIDEr}_{n}(c_{i}, c_{j}) = \frac{1}{4} \sum_{n=1}^{4} \text{CIDEr}_{n}(c_{i}, c_{j}),
\]

where

\[
\text{CIDEr}_{n}(c_{i}, c_{j}) = \frac{\Phi_{n}(c_{i})^{T} \Phi_{n}(c_{j})}{||\Phi_{n}(c_{i})|| \cdot ||\Phi_{n}(c_{j})||}.
\]

In (3), \( \text{CIDEr}_{n} \) is written as the cosine similarity kernel and the corresponding feature space is spanned by \( \Phi_{n}(c) \). Since CIDEr is the average of \( \text{CIDEr}_{n} \) for different \( n \), therefore, it is also a kernel function that accounts for uni-, bi-, tri- and quad-grams.

Since CIDEr can be interpreted as a kernel function, we reconsider the kernel matrix \( K \) in LSA, by using \( k_{ij} = \text{CIDEr}_{n}(c_{i}, c_{j}) \). The diversity according to CIDEr can then be computed by finding the eigenvalues of the kernel matrix \( \{\lambda_{1}, \cdots, \lambda_{m}\} \), computing the ratio \( r = \frac{\sqrt{\lambda_{1}}}{\sum_{i=1}^{m} \sqrt{\lambda_{i}}} \), and applying the mapping function, \( \text{div} = -\log_{m}(r) \). Here, we are computing the diversity by using LSA to find the caption topics in the weighted n-gram feature space, rather than the original BoW space. Other caption similarity measures could also be used in our framework to compute diversity if they can be written as positive definite kernel functions.

4. Experiment Setup

We next present our experiment setup re-evaluating current captioning methods using both diversity and accuracy.

4.1. Generating Diverse Captions

As most current models are trained to generate a single caption, we first must adapt them to generate a set of diverse captions. In this paper we propose 4 approaches to generate diverse captions from a baseline model. (1) Random sampling (RS): After training, a set of captions is generated by randomly sampling word-by-word from the learned conditional distribution \( \hat{p}(c|I) \). (2) Randomly cropped images (RCI): The image is resized to \( 256 \times 256 \), and then randomly cropped to \( 224 \times 224 \) as input to generate the caption. (3) Gaussian noise corruption (GNC): Gaussian noise with different standard deviations is added to the input
image when predicting the caption. (4) Synonym switch (SS): The above 3 approaches manipulate images to generate diverse captions, whereas the synonym switch approach directly manipulates a generated caption. First, a word2vec model is trained on MSCOCO. Next, given a caption, the top-10 synonyms for each word are retrieved and given a weight based on the similarities of their word2vec representation. Finally, with probability $p$, each word is randomly switched with one of its 10 synonyms, where the synonyms are sampled according to their weights.

For the models that are able to generate diverse captions, such as CVAE and CGAN, different random vectors (DRV) are drawn from Gaussian distributions with different standard deviations to generate the captions.

### 4.2. Implementation Details

In this paper, we evaluate the following captioning models: (1) NIC [29] with VGG16 [27]; (2) SoftAtt [34] with VGG16; (3) AdapAtt [19] with VGG16; (4) Att2in [23] with cross-entropy (XE) and CIDEr reward, denoted as Att2in(XE) and Att2in(C); (5) FC [23] with cross-entropy and CIDEr reward, denoted as FC(XE) and FC(C); (6) Att2in and FC with retrieval reward [20], denoted as Att2in(D5) and FC(D5), where the retrieval reward weight is 5 (the CIDEr reward weight is 1), and likewise for D10; (7) CVAE and GMVCVAE [30]; (8) CGAN [5].

Models (1)-(7) generate single caption for one image, and model (7) and (8) are able to generate diverse captions. The models are trained using Karpathy’s training split of MSCOCO. We use each of the models to generate 10 captions for each image in the Karpathy’s test split, which contains 5,000 images. The standard deviations of Gaussian noise for GNC and DRV are $\{1.0, 2.0, \cdots, 10.0\}$. For SS, we first generate a caption using beam search with beam-width 3, and then generate the other 9 captions by switching words with synonyms with probability $p \in \{0.1, 0.15, \cdots, 0.5\}$. Models and diversity generators are denoted as “model-generator”, e.g., “NIC-RS”.

The accuracy $\text{acc}$ of the generated captions $C$ is the average CIDEr: $\frac{1}{m} \sum_{i=1}^{m} \text{CIDEr}(c_i, C_{GT})$, where $c_i \in C$ and $C_{GT}$ is the set of human annotations. We also compute the leave-one-out accuracy of human annotations: $\frac{1}{n} \sum_{i=1}^{n} \text{CIDEr}(g_i, C_{GT\setminus i})$, where $g_i \in C_{GT}$ and $C_{GT\setminus i}$ is the set of human annotations without the i-th annotation. The diversity of $C$ is computed using the LSA-based method (denoted as LSA) and the kernel CIDEr method (denoted as Self-CIDEr), introduced in Sections 3.1 and 3.2.

### 5. Experiment Results

We next present our experiment results evaluating methods on both diversity and accuracy.

---

2https://github.com/ruotianluo/DiscCaptioning
3https://github.com/yiyang92/vae_captioning

![Figure 2: The vocabulary sizes and diversity scores (Self-CIDEr) of different caption models. The vocabulary of each trained model is collected from 50,000 captions (10 captions for each image), while the human annotations have 25,000 captions (5 captions for each image). For GNC, RCI, CVAE, GMVCVAE and CGAN, greedy search is used to generate captions.](image)

![Figure 3: Word frequency plots for the top 5,000 most-frequent words for each captioning model.](image)
using CIDEr reward to fine-tune the model will drastically decrease the vocabulary size so as to improve the accuracy metric (CIDEr) [23]. Interestingly, using a retrieval reward gives a larger vocabulary size compared to using the CIDEr reward. Improving retrieval reward encourages semantic similarity, while improving CIDEr reward encourages syntactic similarity, which leads to low diversity. Comparing the CGAN/CVAE methods, CVAE has a smaller vocabulary compared to CGAN and GMMCVAE, which indicates that the latter could generate more diverse captions. Note that the vocabulary sizes only roughly reflects the diversity – a small vocabulary could lead to diverse captions via using different combinations of words. Hence, it is important to look at the pairwise similarity between captions.

Figure 3 shows the frequency plots of each word used by the models. If a model employs diverse words, the plots in Figure 3 should have a long tail. However, most of the models have learned to use around 2,000 common words. In contrast, CGAN and GMMCVAE encourage a long-tail distribution, and in particular the word frequency plot of CGAN is similar to the human annotations. RS tends to give the most words, but also fails to generate fluent sentences. Therefore, we suggest that both accuracy and diversity should be considered when evaluating a model. Interestingly, there is a very large gap between using cross-entropy and CIDEr rewards for reinforcement learning, which is bridged by the retrieval reward. In Section 5.3, we will show that balancing cross-entropy, CIDEr, and retrieval rewards can also provide good results in terms of diversity and accuracy.

5.2. Considering Diversity and Accuracy

Here we re-evaluate the models accounting for both diversity and accuracy. Figure 4 shows the diversity-accuracy (DA) plots for LSA-based diversity and CIDEr kernelized diversity (Self-CIDEr). The trends of LSA and Self-CIDEr are similar, although LSA yields overall lower values. Hence, we mainly discuss the results of Self-CIDEr.

After considering both diversity and accuracy, we may need to rethink what should be considered a good model. We suggest that a good model should be close to human performance in the DA space. Looking at the performance of humans, the diversity is much higher than Att2in(C), which is considered a state-of-the-art captioning model. On the other hand, the diversity using randomly sampling (RS) are closer to human annotations. However, the accuracy is poor, which indicates that the descriptions are not fluent or are off-topic. Therefore, a good model should well balance between diversity and accuracy. From this point of view, CGAN and GMMCVAE are among the best models, as they are closer to the human annotations in the DA space. Example caption results and their diversity/accuracy metrics can be found in the supplemental.

Most of the current state-of-the-art models are located in the bottom-right of the DA space, (high CIDEr score but poor diversity), as they aim to improve the accuracy. For example, directly improving CIDEr reward via RL is a popular approach to obtain higher CIDEr scores [17, 18, 20, 23], but it encourages using common words and phrases (also see Figure 2), which lowers the diversity. Using retrieval reward is able to improve diversity comparatively, e.g., Att2in(D5) vs Att2in(C), because it encourages distinctive words and semantic similarity, and suppresses common syntaxes that do not benefit retrieval. The drawback of using retrieval model is that the fluency of the captions could be poor [20], and using a very large weight for the retrieval reward will cause the model to repeat the distinctive words. Finally, note that there is a large gap between using the cross-entropy loss and the CIDEr reward for training, e.g., Att2in(XE) and Att2in(C). In the next subsection, we will consider building models to fill the performance gap by balancing between the losses.

Comparing the diversity generators, SS and GNC are more promising for generating diverse captions. Captions generated using RCI have higher accuracy, while those using RS have higher diversity. Interestingly, in the top-left of the DA plot, using RS, a more advanced model can generate more accurate captions without reducing the diversity. This shows that an advanced model is able to learn a better \(\hat{p}(c|I)\), which is more similar to the ground-truth distribution \(p(c|I)\). However, there is a long way to go to reach the accuracy of human annotations.

Correlation to human evaluation. We conduct human evaluation on Amazon Machine Turk (AMT). We use 100 images, and for each image we show the worker 9 sets of captions, which are generated in different ways: human annotations and 8 models, AdapAtt-SS, AdapAtt-GNC, AdapAtt-RCI, Att2in(XE)-RS, Att2in(C)-RS, Att2in(D5)-RS, Att2in(D10)-RS and CGAN-DRV. We require the workers to read all the sets of captions and then give scores (from 0 to 1) that reflects the diversity\(^4\) of the set of captions. Each image is evaluated by 3 workers, and the diversity score for each image/model combination is the average score given by the 3 workers.

Fig. 5 (left, center) shows the correlation plots between our proposed metrics and human evaluation. The overall consistency between the proposed diversity metric and the human judgement is quantified using Pearson’s (paramet-

\[ \text{Table 2: Correlation between computed diversity metric and human diversity judgement: (top) overall correlation; (bottom) correlation of per-image rankings of methods.} \]

\(^4\)In our instructions, diversity refers to different words, phrases, sentence structures, semantics or other factors that impact diversity.
Figure 4: The performance of different models considering accuracy and diversity. Left: using LSA-based diversity, which employs BoW features. Right: using CIDEr kernelized diversity (Self-CIDEr). The marker shape indicates the caption model, while the marker color indicates the diversity generator or training method.

![Figure 4](image)

Figure 5: The correlation plots between the diversity scores computed by different metrics and human evaluation. The red lines are the best fit lines to the data.

![Figure 5](image)

We compare our metrics with $mBLEU_{mix} = 1 - \frac{1}{3} \sum_{n=1}^{4} mBLEU_n$, which accounts for $mBLEU_{\{1,2,3,4\}}$, and we invert the score so that it is consistent with our diversity metrics (higher values indicate more diversity). The correlation plot between $mBLEU_{mix}$ and human judgement is shown in Fig. 5 (right). $mBLEU_{mix}$ has lower correlation coefficient with human judgement, compared to LSA and Self-CIDEr (see Table 2). Similar results are obtained when looking at the $mBLEU_n$ scores. Self-CIDEr has better overall correlation with human judgement, while the two methods are comparable in terms of per-image consistency of method ranking.

In addition the correlation plot shows the $mBLEU$ scale is not uniformly varying, with more points falling at the lower and higher ends of the scale and less points in the middle. In contrast, LSA and Self-CIDEr have more uniform scales.

5.3. Re-thinking Reinforcement Learning

In this subsection we further investigate RL for image captioning, and how to bridge the gap between the perfor-
Figure 6: The diversity and accuracy performance of Att2in (left) and FC (right) with different loss functions. XE, CIDEr, and Retrieval denote the cross-entropy loss, CIDEr reward, and retrieval reward. The weights are \(\lambda \in \{0, 1, 2, 3, 5, 10, 20\}\), \(\beta \in \{0, 1, 2, 3, 5, 10, 15\}\), \(\alpha \in \{0, 5, 10, 20, 30, 40, 50\}\), \(\gamma \in \{0, 10, 20, 30, 40, 50\}\) and \(\zeta \in \{0, 5, 10, 20, 30, 40, 50\}\). The inset plot in the bottom-left is a zoom-in of rectangle in the main plot.

Figure 7: MDS visualization of the similarity between captions of 10 images. 10 captions are randomly sampled from Att2in for each image. Markers and colors indicate different images. Larger markers indicates multiple captions located at the same position.

6. Conclusion

In this paper, we have developed a new metric for evaluating the diversity of a caption set generated for an image. Our diversity measure is based on computing singular values (or eigenvalues) of the kernel matrix composed of CIDEr values between all pairs of captions, which is interpretable as performing LSA on the weighted n-gram feature representation to extract the topic-structure of the captions. Using our diversity metric and CIDEr to re-evaluate recent captioning models, we found that: 1) models that have optimized accuracy tend to have very low diversity, and there is a large gap between model and human performances; 2) balancing the XE loss and other reward functions when using RL is a promising way to generate diverse and accurate captions, which can achieve performance that is on par with generative models (CGAN and GMMCVAE).
